High-sensitivity isothermal titration calorimetry (ITC) has opened a new avenue to efficiently study the mechanisms of peptide-membrane interaction. A wide variety of interactions has been found which range from hydrophobic insertion (*cyclosporin A*, an immuno-suppressant) over electrostatic adsorption (*somatostatin*, a peptide hormone; *nisin*, a bacterial antibiotic; *substance P*, a pain transmitter) to cooperative β -structured aggregation at the membrane surface (β *APP(1-40)*, a peptide of Alzheimer plaques) and membrane induced random coil \rightarrow α -helix transitions (*magainin*, an antibiotic; *ApoA1*, a lipoprotein involved in lipid transport). A comparison of the thermodynamic data reveals a graded transition from entropy-driven to enthalpy-driven reactions.

The thermodynamics of the helix-coil transition at the membrane surface was investigated with the antibiotic *magainin 2 amide (M2a)*. The helix content of *M2a* was systematically varied by substituting two adjacent amino acids by their D-enantiomers. The thermodynamic parameters of *M2a* binding to the membrane are linearly related to the helicity. Helix formation can be described with the Zimm-Bragg theory, is a strong driving force of peptide insertion into the membrane, and accounts for about 50% of the free energy of binding.

A cooperative process is also found for β AP(1-40), a major component of Alzheimer plaques. ITC and circular dichroism detect a random coil \leftrightarrow β -sheet aggregation at the surface of negatively charged membranes. The cationic peptide is attracted to the membrane surface. The increase in peptide concentration together with the membrane surface acting as a template then leads to the formation of large β -structured aggregates.
